Aberrant T-cell activation underlies many autoimmune disorders, yet most attempts to induce T-cell tolerance have failed. Building on previous strategies for tolerance induction that exploited natural mechanisms for clearing apoptotic debris, we show that antigen-decorated microparticles (500-nm diameter) induce long-term T-cell tolerance in mice with relapsing experimental autoimmune encephalomyelitis. Specifically, intravenous infusion of either polystyrene or biodegradable poly(lactide-co-glycolide) microparticles bearing encephalitogenic peptides prevents the onset and modifies the course of the disease. These beneficial effects require microparticle uptake by marginal zone macrophages expressing the scavenger receptor MARCO and are mediated in part by the activity of regulatory T cells, abortive T-cell activation and T-cell anergy. Together these data highlight the potential for using microparticles to target natural apoptotic clearance pathways to inactivate pathogenic T cells and halt the disease process in autoimmunity.

Autoimmune diseases, such as multiple sclerosis, psoriasis, rheumatoid arthritis and type 1 diabetes, are the third ranked cause of human morbidity and mortality in the United States1. In these disorders, a failure in immune regulation results in T cell–mediated destruction of self tissues. The pathologic role of T cells in driving autoimmune diseases has resulted in numerous therapies aimed at inactivating T cells. The induction of long-term, durable antigen-specific T-cell tolerance is the ideal therapy, but published ‘tolerance-inducing’ strategies such as T cell epitope–specific peptides, T cell–specific antibodies or co-stimulation blockade2–4 have not fared well clinically5–8. Each failure was caused by issues associated specifically with the particular target and agent; however, many also involved concerns about safety and marginal efficacy. For example, cytokine release syndrome has been a common issue with the use of monoclonal antibody–based treatments, whereas soluble peptide infusion has induced anaphylactic responses in mouse models9.

We previously reported that intravenous administration of soluble peptides crosslinked to syngeneic splenic leukocytes using ethylene carbodiimide (ECDI) safely and efficiently induces antigen–specific immune tolerance, is effective in the prevention and treatment of T helper type 1 (Th1) cell– and/or Th17 cell–mediated autoimmune diseases and overcomes many of the drawbacks of the failed trials involving monoclonal antibodies and soluble peptides10–12. This strategy has recently been proven safe in a phase 1 clinical trial in patients with multiple sclerosis (S.D.M., unpublished data). However, the challenge of isolating isologous leukocytes and peptide coupling under good manufacturing practices (GMP) may inhibit clinical application of this therapy. The mechanism underpinning the beneficial effect of this strategy involves the delivery of an antigen in the context of apoptotic carrier cells11,12. Therefore, we sought to achieve similar results using inert microparticles (500-nm diameter) instead of apoptotic cells. Microparticles do not have the stability, manufacturing, storage and other issues that complicate clinical translation of apoptotic cell–based therapies. A number of microparticle-based approaches designed to delay the release of small-molecule therapeutics have recently been approved by the US Food and Drug Administration13.

Microparticles have also been used as adjuvants14. Here we show that microparticles coupled to encephalitogenic myelin epitopes prevent and treat the clinical symptoms of experimental autoimmune encephalomyelitis (EAE), a mouse model of multiple sclerosis. This treatment reduces inflammatory cell infiltration into and damage of the central nervous system (CNS). The beneficial effect of the microparticles requires the scavenger receptor MARCO, as mice deficient in MARCO are resistant to tolerance induced by antigen-linked microparticles but not by soluble peptide or antigen-coupled apoptotic cells. Furthermore, tolerance induced by peptide-coupled microparticles depends on both the induction of T-cell anergy and the activity of regulatory T (Treg) cells.

Collectively, this work demonstrates that antigen-linked microparticles might represent an alternative way to treat T cell–based autoimmune disorders by inducing T-cell tolerance.

RESULTS
Antigen-linked polystyrene beads prevent and treat EAE
The removal of apoptotic debris normally occurs without immune activation. We have previously shown that intravenously (i.v.) administered apoptotic cells localize to the splenic marginal zone, where they mediate changes in scavenger receptor expression and upregulate interleukin-10 (IL-10) production. Antigen-coupled apoptotic cell tolerance requires upregulation IL-10 production by macrophages, induction of Treg cells and co-inhibition of T cells through the CTLA-4 and PD-1 pathways. It is therefore crucial to identify a particle carrier that localizes to similar areas of the spleen and does not trigger immune activation pathways. We postulated that peptide-coupled syngeneic splenic leukocytes (antigen-splenocyte, Ag-SP) could be replaced by inert microparticles covalently linked with antigen.

We thus tested the ability of carboxylated 500-nm polystyrene beads (PSB) coupled with the immunodominant myelin proteolipid protein PLP$_{139-151}$ epitope (PLP$_{139-151}$-PSB) to induce tolerance for the prevention and treatment of relapsing-remitting EAE (R-EAE). In this mouse model of relapsing-remitting multiple sclerosis, SJL/J mice are injected with PLP$_{139-151}$ in adjuvant initiating an autoantibody-CLR-phenotypic CD4$^+$ T-cell response leading to the primary disease phase characterized by hindlimb paralysis. Mice then spontaneously remit from acute disease, although the tissue damage resulting from the primary response promotes the activation of T cells targeting a second PLP epitope, PLP$_{178-191}$. This phenomenon is termed ‘epitope spreading’ and subsequently causes a second round (relapse) of hindlimb paralysis. In the same way, if mice are initially injected with PLP$_{178-191}$ (the subdominant epitope), PLP$_{139-151}$ will function as the spread epitope. Injection of PLP$_{139-151}$-SP or PLP$_{139-151}$-PSB, but not PSB coupled with an irrelevant ovalbumin peptide (OVA$_{323-339}$), 7 d before the initiation of disease protected the mice from disease (Fig. 1a). Treatment with PLP$_{139-151}$-PSB at the first sign of symptoms
(11 d after induction of disease) also prevented disease initiation in the vast majority of mice (Fig. 1b), and this effect lasted for at least 66 d (Fig. 1c). Although injection of PLP\textsubscript{139-151}-PSB 7 d before injection of PLP\textsubscript{178-191} mixed with complete Freund’s adjuvant (CFA) did not prevent acute disease, indicating the antigen specificity of the tolerance, it did prevent relapse (Fig. 1d), indicating that this treatment could prevent epitope spreading.

Treatment with PLP peptide–coupled PSB affected T-cell function. For example, we showed inactivation of myelin-specific CD4\textsuperscript+ T cells by a lack of delayed-type hypersensitivity (DTH) responses, an in vitro measure of CD4\textsuperscript+ T-cell function, to both the immunizing (PLP\textsubscript{139-151}) and spread epitope (PLP\textsubscript{178-191}) (Fig. 1e,f). Treatment with PLP\textsubscript{139-151}-PSB also reduced leukocyte (CD45\textsuperscript×) and CD4\textsuperscript+ T-cell infiltration of the CNS (Fig. 1g,h). In addition, similarly to Ag-SP, Ag-PSB did not result in anaphylactic responses in mice with established disease unlike administration of soluble peptides.

We next addressed the importance of covalent peptide linkage, microparticle size and route of administration. Covalent linkage with ECDI was essential, as PSB incubated with PLP\textsubscript{139-151} in the absence of ECDI had no impact on disease (Fig. 1i). Normalizing for peptide mass (with each dose containing 20 \mu g of peptide), we coupled PLP\textsubscript{139-151} to particles with varying diameters (Fig. 1j). Although 4.5-\mu m and 1.75-\mu m diameter particles provided some disease modification, optimal disease protection was conferred by treatment with the standard 500-nm PLP\textsubscript{139-151}-PSB, whereas 100-nm PLP\textsubscript{139-151}-PSB prevented relapse but did not confer any protection during acute disease. In addition, similarly to Ag-SP\textsuperscript{12}, intravenous but not subcutaneous administration of PLP\textsubscript{139-151}-PSB protected against PLP\textsubscript{139-151}-initiated disease (Fig. 1k) and prevented \textit{in vitro} antigen-specific T-cell–recall responses (Fig. 1l).

**MARCO mediates tolerance induction**

The influence of microparticle size and administration route suggests that interactions with phagocytic cells in the splenic marginal zone may be crucial for microparticle-induced tolerance. We previously showed that the infusion of apoptotic debris upregulates the expression of select scavenger receptors, such as MARCO, in the spleen\textsuperscript{12}. Scavenger receptors comprise a set of structurally diverse proteins, expressed predominately by phagocytes, that are important in the clearance of modified lipid particles and polyanionic ligands of both host and pathogen origin\textsuperscript{19}. MARCO contributes to the uptake and clearance of particulate debris\textsuperscript{20,21}. We found that fluorescein isothiocyanate (FITC)-labeled PLP\textsubscript{139-151}-PSB administered i.v. localized with MARCO\textsuperscript* cells in the splenic marginal zone, presumably the highly phagocytic marginal zone macrophages (MZMs) (Fig. 2c). The cells containing FITC-labeled PLP\textsubscript{139-151}-PSB also expressed SIGN-R1, the murine homolog of DC-SIGN (Fig. 2e), that is expressed by MZMs with professional antigen-presenting capabilities\textsuperscript{22,23}, but they did not express SIGLEC-1, a marker that defines metallophilic macrophages (Fig. 2e). Overall, the data indicate that PLP\textsubscript{139-151}-PSB administered i.v. localizes to MARCO\textsuperscript* MZMs.

We confirmed the importance of MARCO in peptide-coupled particle tolerance using MARCO-deficient (Marco\textsuperscript{−/−}) BALB/c mice. Specifically, OVA\textsubscript{323-339}-PSB administered i.v. resulted in a decreased DTH response to subcutaneously (s.c.) injected OVA\textsubscript{323-339} and CFA in wild-type (WT) but not Marco\textsuperscript{−/−} BALB/c mice (Fig. 2g). A role for MARCO in T-cell tolerance has not previously been defined. Thus, we further examined whether Marco\textsuperscript{−/−} mice were resistant to other forms of tolerance induction. Similarly to WT mice, Marco\textsuperscript{−/−} mice could betolerized by infusion of soluble OVA\textsubscript{323-339} (Fig. 2h) or OVA\textsubscript{323-339}-SP (Fig. 2i). Cumulatively, the data show the importance of MARCO in T-cell tolerance induced by Ag-PSB. However, these findings indicate that soluble peptides and apoptotic Ag-SP induce tolerance through different mechanisms that probably involve different antigen uptake receptors.

**T-cell extravasation**

We next determined the temporal and kinetic effects of Ag-PSB infusion on circulating T cells using DO11.10 OVA\textsubscript{323-339}-specific T-cell receptor (TCR) transgenic mice and beads coupled to OVA\textsubscript{323-339}. We selected DO11.10 mice for this study to eliminate potential variables related to diverse TCR repertoires and/or the potential for self reactivity. OVA\textsubscript{323-339}-PSB administered i.v. triggered a rapid and sustained decrease in the number of OVA\textsubscript{323-339}-specific CD4\textsuperscript+ T cells in the peripheral blood commensurate with a slight increase in the number of T cells in the spleen and lymph nodes (Fig. 3a and Supplementary Fig. 1). This reduction was antigen specific, as it was not induced by intravenous administration of myelin basic protein (MBP)\textsubscript{84-99}-PSB (Fig. 3a). In addition, T cells in the blood and secondary lymphoid organs of these mice showed functional differences. T cells isolated from the lymph nodes, but not from the blood, of DO11.10 mice that had been i.v. injected with OVA\textsubscript{323-339}-PSB were hypoproliferative in response to OVA\textsubscript{323-339} stimulation (Fig. 3b,c). These data imply that T-cell tolerance may require T-cell interaction with some cell populations located in the secondary lymphoid organs.
Role of T<sub>reg</sub> cells and IL-10

We have previously shown that the T-cell tolerance induced by intravenous administration of peptides crosslinked to splen leakocytes was partially dependent on IL-10 and the activity of antigen-specific CD4<sup>+</sup>CD25<sup>+</sup>Foxp3<sup>+</sup> T<sub>reg</sub> cells<sup>12</sup>. Neutralization of IL-10 at the time of PLP<sub>39–151</sub>-PSB infusion had only a marginal effect on tolerance induction (Fig. 3d). However, functional inactivation of T<sub>reg</sub> cells by treatment with the CD25-specific antibody PC61 (ref. 25) before PLP<sub>39–151</sub>-PSB infusion resulted in a modest but significant (P < 0.05, analysis of variance (ANOVA)) and reproducible reversal of the amount of protection during acute disease (Fig. 3e). These results suggest that regulatory T cells have an important, but redundant, role in PSB-induced tolerance, as treatment with CD25-specific antibodies only partially blocked tolerance induction. IL-10 seems to make only modest contributions to PSB-induced tolerance.

T-cell abortive activation and anergy

To further explore the effects of these microparticles on T-cell proliferation and differentiation, we adoptively transferred carboxyfluorescein diacetate succinimidyl diester (CFSE)-labeled PLP<sub>39–151</sub>-specific transgenic (5B6) T cells into naïve SJL/J mice. Forty-eight hours later, we i.v. injected 9 × 10<sup>5</sup> PLP<sub>39–151</sub>-PSB or OVA<sub>323–339</sub>-PSB or s.c. injected PLP<sub>39–151</sub> along with CFA. PLP<sub>39–151</sub>-specific T cells isolated from the spleen and lymph nodes of PLP<sub>39–151</sub>-PSB–treated mice showed markedly reduced proliferation (CFSE dilution) in terms of both the percentage of total cells divided and the number of divisions per cell compared to cells from mice injected with PLP<sub>39–151</sub> plus CFA (Fig. 4a–iv). Notably, this effect was antigen specific, as T cells from mice injected with OVA<sub>323–339</sub>-PSB did not show any CFSE dilution (Fig. 4a–vi). We injected a subset of mice first i.v. with PLP<sub>39–151</sub>-PSB or OVA<sub>323–339</sub>-PSB and then s.c. with PLP<sub>39–151</sub> plus CFA. T cells from mice injected with PLP<sub>39–151</sub>-PSB before PLP<sub>39–151</sub> plus CFA proliferated less than those from mice injected with PLP<sub>39–151</sub> plus CFA alone (Fig. 4a,b).

The muted proliferation induced by peptide-coupled particle infusion suggests that tolerance may be induced by abortive T-cell activation. After adoptive transfer into naïve SJL/J mice, PLP<sub>39–151</sub>-specific T cells isolated from mice injected i.v. with PLP<sub>39–151</sub>-PSB showed classical T-cell activation phenotypes: upregulated expression of CD69 and CD44 and downregulated expression of CD62L (Fig. 5a,b). Notably, a larger fraction of splenic PLP<sub>39–151</sub>-specific T cells expressed CD69 in mice injected i.v. with PLP<sub>39–151</sub>-PSB than in mice injected s.c. with PLP<sub>39–151</sub> plus CFA (Fig. 5a). However, the opposite was true with regard to CD44 expression (Fig. 5b). In addition, T cells in mice i.v. administered PLP<sub>39–151</sub>-PSB produced neither interferon-γ (IFN-γ) nor IL-17, whereas cells in mice injected s.c. with PLP<sub>39–151</sub> and CFA produced both of these cytokines (Fig. 5c,d). Furthermore, T cells from mice injected i.v. with PLP<sub>39–151</sub>-PSB produced minimal IL-17 and IFN-γ, even when the recipient mice were challenged s.c. with PLP<sub>39–151</sub> plus CFA 5 d later (Fig. 5c,d), as shown by OVA<sub>323–339</sub> injection, this effect was antigen specific. Together these findings suggest that PLP<sub>39–151</sub>-PSB induce abortive T-cell activation.

Figure 3 Response of antigen-specific T cells to tolerance induction with Ag-PSB. (a) T cell content 48, 39 and 168 h after treatment in female DO11.10 OVA<sub>323–339</sub>-specific TCR transgenic mice treated i.v. with 500-nm carboxyfluorescein diacetate succinimidyl diester (CFSE)-labeled PLP<sub>39–151</sub>-PSB or an irrelevant peptide (MBP<sub>85–99</sub>) and re-stimulated 48 h later with 1 mg ml<sup>–1</sup> cognate OVA<sub>323–339</sub> peptide or PLP<sub>39–151</sub> in vitro. (b) Mean clinical score in naïve SJL/J mice treated with control immunoglobulin (Cont. Ig) or anti–IL-10 (JES5-16E3; 200 μg intraperitoneally (i.p.)) (d) or control immunoglobulin or anti-CD25 (PC61; 500 μg i.p.) (e) 1 d before and 1 d after treatment with either OVA<sub>323–339</sub>-PSB or PLP<sub>39–151</sub>-PSB (PLP139-PSB); 7 d after tolerization, mice were primed for EAE with PLP<sub>39–151</sub> plus CFA. Data are representative of three separate experiments. Error bars, s.e.m. *P < 0.05 (Student’s t test) for the differences in T cell numbers, CFPM and mean clinical scores compared to the responses to tolerized to the appropriate irrelevant control peptide.

Figure 4 Antigen-specific T cells undergo suboptimal proliferation in response to Ag-PSB. (a) Results from naive SJL/J (CD90.2<sup>+</sup>) recipient mice exposed i.v. to PLP<sub>39–151</sub>-PSB (i.i.) s.c. to PLP<sub>39–151</sub> plus CFA (iii, iv) or i.v. to OVA<sub>323–339</sub>-PSB (v, vi) 48 h after being transferred with naïve CD90.1<sup>+</sup> PLP<sub>39–151</sub>-specific 5B6 TCR transgenic T cells sorted from donor lymph nodes and labeled with CFSE. Five days after these treatments (P.I.), spleens and lymph nodes (LNs) were collected, and the percentage of dividing CD90.1<sup>+</sup> T cells was assessed by measuring CFSE dilution using flow cytometry. (b) Flow cytometric analysis of CFSE dilution at 5 d after priming in mice additionally treated with PLP<sub>39–151</sub>-PSB (ii) or OVA<sub>323–339</sub>-PSB (iii, iv) 5 d after the initial treatments in a and then primed with PLP<sub>39–151</sub> plus CFA. Three separate mice were analyzed in each group with representative plots shown. Data shown are representative of three separate experiments. Percentages in graphs reflect the percent of T cells that have divided.
Anergy has been implicated in the induction of T-cell tolerance. We examined a potential role for clonal anergy in PLP139-151 tolerance. We i.v. injected SJL/J mice with OVA323-339-PSB or PLP139-151-PSB and s.c. injected them with PLP139-151 and CFA 7 d later. We measured then the in vitro T-cell responses to various peptides and cytokines 8 d later. Compared to T cells from OVA323-339-PSB–injected mice, those from PLP139-151–PSB–injected mice showed less proliferation and IFN-γ and IL-17 production after in vitro re-stimulation with PLP139-151. However, these responses were significantly (P < 0.01, ANOVA), but not completely, restored.

Figure 5 Antigen-specific T cells are abortively activated after Ag-PSB encounter but do not synthesize IL-17A and IFN-γ after direct in vivo exposure to Ag-PSB or after subsequent immunogenic stimulation. (a, b) Flow cytometric analyses of T-cell activation markers CD62L, CD69 and CD44 5 d after treatment in spleens and lymph nodes (LNs) from naive CD90.2+ SJL/J recipients that were then treated i.v. with PLP139-151-PSB (PLP139-PSB) or primed s.c. with PLP139-151 plus CFA. Transgenic T cells were identified by CD90.1 and CFSE signals. (c, d) Naive CD90.1+ T cells were CFSE labeled and transferred to naive CD90.2+ recipient mice. Twenty-four h later, recipients were monitored for development of clinical disease by assessing mean clinical score (*). Results are representative of three independent experiments.

Figure 6 Short-term tolerance induced by i.v. treatment with Ag-PSB is caused primarily by anergy induction. (a–c) SJL/J mice were treated i.v. with OVA323-339-PSB (OVA323-PSB) or PLP139-151-PSB (PLP139-PSB) 7 d before s.c. priming with PLP139-151 plus CFA. Eight days after priming, the proliferation of spleen and lymph nodes in response to stimulation with the priming antigen (PLP139-151) or a control antigen (OVA323-339) in the presence of absence of 200 U ml−1 of exogenous IL-2 was measured (a). Supernatants were collected for measurements of secreted IFN-γ (b) and IL-17A (c). Results are representative of 3–4 separate experiments. (d–f) SJL/J mice were treated with 500-nm FITC-PSB (d) or 500-nm biodegradable FITC-PLG microparticles (e) coupled with PLP139-151. Twelve hours later, frozen spleen sections were prepared from a subset of mice, and these sections were counterstained with DAPI (blue). (f–i) On day +7 (f–h) or day +11 (i) relative to PLP139-151 plus CFA priming, mice were injected with 500-nm PLP139-151-PSB or PLP139-151-PLG (PLP139-PLG) microparticles and monitored for development of clinical disease by assessing mean clinical score (f) and cumulative mean clinical score (g) over time. At the conclusion of the experiment, the mice from f were ear challenged with PLP139-151, and DTH responses were determined. (j–k) SJL/J mice were tolerized with 500-nm PLP178-191-PLG (PLP178-PLG) or OVA323-339-PLG (OVA323-PLG) microparticles on day +25 after PLP139-151 plus CFA priming (j) or with 500-nm PLP139-151-PLG or OVA323-339-PLG microparticles on day +18 after PLP139-151 plus CFA priming (k) and monitored for clinical disease. Error bars, s.e.m. *P < 0.01 (ANOVA) for the differences in proliferation, mean clinical scores and DTH responses compared to groups tolerized to sham PLG particles. Data shown are representative of 2–3 separate experiments of 5–7 mice per group.
by the addition of exogenous IL-2 to the cultures. (Fig. 6a–c). Thus, antigenic peptides coupled to microparticles are capable of inducing T-cell anergy, which can be overcome in vitro through the addition of exogenous IL-2 (ref. 26).

**Biodegradable microparticles induce T-cell tolerance**

Our data highlight the ability of polystyrene microparticles to serve as antigen carriers to induce T-cell tolerance. To determine whether T-cell tolerance can also be induced with biocompatible, biodegradable microparticles, we tested particles made of the US Food and Drug Administration–approved material poly(lactide-co-glycolide) (PLG). PLG is stable and considered to be immunologically inert. Similarly to PLP<sub>139-151</sub>-PSB, PLP<sub>139-151</sub>-PLG administered i.v. localized to the splenic marginal zone (Fig. 6d–e). When administered prophylactically, PLP<sub>139-151</sub>-PLG administered i.v. reduced EAE clinical scores and PLP-specific DTH responses (Fig. 6f–h). We were also able to treat ongoing EAE disease with i.v. administration of PLP<sub>139-151</sub>-PLG. (Fig. 6i).

We then tested whether microparticles coupled with the appropriate relapse-associated myelin epitopes could inhibit disease relapse when administered during disease remission. Intravenous administration of PLP<sub>178-191</sub>-PLG 25 d after s.c. injection of PLP<sub>139-151</sub> and CFA reduced the severity of relapse symptoms (Fig. 6j), as did infusion of PLP<sub>139-151</sub>-PLG 18 d after s.c. injection of PLP<sub>178-191</sub> and CFA (Fig. 6k).

**DISCUSSION**

We found previously that antigenic peptides coupled to splenic leukocytes can be used as treatments in preclinical models of autoimmune disease, allergy and transplantation<sup>12,18,27,28</sup>. This technique is currently being evaluated in the clinic for treatment of multiple sclerosis. However, the complexity and cost of producing antigen–coupled cells under GMP conditions may impede clinical translation. We undertook the current study to determine whether inert microparticles could be used as surrogates for apoptotic leukocytes as antigen ‘carriers’. Inert microparticles coupled to peptides, unlike Ag-SP, can be produced in large amounts under GMP conditions. We demonstrate that both polystyrene and biodegradable PLG microparticles are highly efficient substitutes for apoptotic cells, as they are taken up in a MARCO scavenger receptor–dependent fashion and are capable of inducing long-term antigen-specific T-cell abortive activation and anergy.

To avoid complications of immunosuppression, the ability to tolerate T cells specific for autoantigens and alloantigens remains the desired treatment for a myriad of immune-mediated diseases. However, the translatability of the tolerance approaches demonstrated to be efficacious in animal studies has been lacking. Intravenous administration of anti-CD3 to induce tolerance in type 1 diabetes has resulted in questionable efficacy and safety concerns<sup>29</sup>. Attempts to potentially overcome some of these barriers through oral administration are under way, and some positive data have been obtained in small study involving 15 patients<sup>30</sup>. Initial studies using anti-CD3 to treat type 1 diabetes also showed similar positive outcomes<sup>32</sup>; therefore, larger patient studies will be needed to clearly define any clinical benefit of oral over intravenous anti-CD3 treatment.

A number of antigen–specific approaches to generate tolerance have previously been tested in autoimmune diseases. Intradermal administration of CGP77116, an altered peptide ligand of MBP<sub>83–99</sub> worsened symptoms in three patients with multiple sclerosis because in at least two of the patients there were<sup>8</sup> increased immune responses to MBP<sub>83–99</sub>. Attempts to induce ‘high-zone tolerance’<sup>31</sup> by i.v. (MBP<sub>8298</sub>) infusion of a large bolus of peptide recently failed a phase 3 clinical trial in patients with multiple sclerosis<sup>32</sup>. Similarly, in type 1 diabetes, s.c. injection of the 65-kDa isofrom of glutamic acid decarboxylase in alun had no effect on disease progression<sup>33</sup>. Murine antigen delivery has also shown promise in animal models of multiple sclerosis and type 1 diabetes<sup>34–36</sup>, but larger clinical trials testing oral and nasal administration of insulin have been ineffective in the prevention or reversal of new-onset type 1 diabetes<sup>35,36</sup>

Two DNA vaccines are also in development for treating patients with multiple sclerosis. BHT3009 encodes full-length MBP. In a phase 2 study, BHT3009 was administered at weeks 0, 2 and 4 and then monthly by s.c. injection. Although this treatment did not alter the relative risk for relapse or first time to relapse, there was a reduction in new CNS lesions<sup>37</sup>. The reduction in lesion formation was most prominent in patients that had high concentrations of antibodies targeting MBP, whereas patients with low anti-MBP titers had a similar rate of lesion formation as placebo-treated controls. Although further studies are needed to confirm the potential utility of BHT3009, the existence of a patient population that may not be responsive to BHT3009 supports the need for other therapeutic modalities.

A second DNA vaccine, ATX-MS-1467, expresses peptides that are thought to mimic processed myelin antigens and therefore act similarly to glatiramer acetate (GLAT), a random-length polymer of four amino acids (glutamic acid, lysine, alanine and tyrosine) found in MBP, which has been shown to compete with myelin peptides for access to the peptide binding cleft in the MHC complex<sup>38</sup>, promote T<sub>H</sub>2 cell responses and induce IL-10–producing T<sub>reg</sub> cells<sup>39</sup>. These effects are not antigen specific, and as such, it may be predicted that the efficacy of ATX-MS-1467 may be similar to that of GLAT, resulting in a 50% reduction in multiple sclerosis relapses in responsive patients<sup>38</sup>

Our data showing the requirement for peptides to be covalently linked to 500-nm particles and confirming the importance of i.v. administration for efficient tolerance induction<sup>12</sup> reinforce the importance of delivering the antigen-linked particles to the splenic marginal zone. As a possible explanation of the particle size requirement, it has been reported that compared to 20-nm diameter particles, 200-nm and 1,000-nm diameter particles have a higher propensity to bind to MARCO in vitro<sup>40</sup>. We show that MARCO-expressing MZM, but not SIGLEC-1–expressing metallophilic macrophages, take up peptide-linked particles. To our knowledge, MARCO has not previously been ascribed a role in T-cell tolerance, although this receptor was previously implicated in the pathogenesis of systemic lupus erythematosus; in systemic lupus erythematosus, it is postulated that failure of MARCO to remove apoptotic debris has a potential role in autoantibody formation<sup>41,42</sup>. MARCO is also important for the uptake of bacteria<sup>43</sup>, silica particles<sup>44</sup> and polymer-based microparticles<sup>45</sup>. We speculate that MARCO functions through its ability to take up antigen–linked particles and assist in macrophage antigen presentation and/or antigen transfer to local dendritic cells. MARCO may also inhibit inflammatory responses by preventing dendritic cell migration<sup>45</sup> or by other unknown anti-inflammatory mechanisms<sup>46</sup>. However, although macrophage production of IL-10 is thought to be crucial for tolerance to apoptotic cells<sup>12</sup>, IL-10 neutralization failed to completely inhibit the tolerance induced by antigenic peptides coupled to microparticles. In addition, it seems that the MARCO pathway of tolerance induction is limited to microparticle-bound peptide, as MARCO<sup>−/−</sup> mice were effectively tolerated to soluble peptide and peptides coupled to apoptotic splenic leukocytes.

PLP<sub>139-151</sub>-PSB infusion triggered antigen–specific T-cell extravasation into the lymphoid compartment. This extravasation was notable,
as T cells isolated from the peripheral blood but not the lymph nodes within 48 h after treatment remained highly reactive to self antigen. This is probably the result of the inability of T cells to interact with tolerogenic antigen-presenting cells and/or Treg cells while in the laminar flow of the blood. In addition, PLP139–151-PSB infusion resulted in suboptimal PLP139–151-specific T-cell proliferation, cytokine production and activation in general. T-cell anergy was also induced, as nonresponsiveness could be largely reversed through the addition of exogenous IL-2 (refs. 26,47). Functional inactivation of Treg cells partially prevented the tolerance induced by antigenic peptide-coupled microparticles, which is in line with our previous studies using splenic leukocytes12. Upregulation of PD-L1 expression on splenic macrophages was implicated in our previous work, but we found only slight upregulation of PD-L1 expression on macrophages in mice treated with antigenic peptides coupled to microparticles (data not shown). Future experiments are required to further delineate the role of PD-L1 and CTLA-4 in antigen-coupled particle tolerance17.

Clinical translation of tolerance-based therapies for the treatment of autoimmune disease requires the ability to suppress pre-existing autoreactive effector T cells and/or establish tolerance of naive autoreactive T cells that may be activated after exposure to endogenous autoantigens released from damaged target organs (epitope spreading)19. Here we show that i.v. administration of PLP139–151-PSB can prophylactically prevent R-EAE, inhibit established R-EAE and suppress relapse caused by epitope spreading.

This study supports the use of antigen-coupled microparticles as a tool for tolerance induction. This option will probably have broad therapeutic utility, with preliminary studies in airway allergy27 and allotolerance18,28 yielding promising results. From a clinical development perspective, identification of specific autoantigens and T-cell epitopes to be targeted in various autoimmune diseases, and a determination of the roles of scavenger receptors in various diseases, remain challenges for further investigations.

METHODS

Methods and any associated references are available in the online version of the paper.

Note: Supplementary information is available in the online version of the paper.

ACKNOWLEDGMENTS

This work was supported by a grant from the Myelin Repair Foundation, US National Institutes of Health grants NS026543 and EB013198, Juvenile Diabetes Research Foundation grant 17-2011-343 and the Australian National Health and Medical Research Foundation grant 176-2011-343 and the Australian National Health and Medical Research Council grants 512413 and 1030897. We also thank V. Kuchroo and L. Kobich of Harvard University for providing transgenic mice.

AUTHOR CONTRIBUTIONS

D.R.G. and A.J.M. designed and performed the majority of the experiments, interpreted results and assisted with manuscript preparation. D.P.M., R.L.T., Z.N.H., W.T.Y. and M.T.G. performed and/or assisted with several experiments. X.L. provided reagents and advice. S.D.M. provided intellectual input, secured the funding and guided experimental design and the preparation of the manuscript with major input from M.P., N.J.C.K. and L.D.S.

ONLINE METHODS

Mice. Female SJL/J mice were purchased from Harlan Laboratories (Indianapolis, IN). Female BALB/c mice were purchased from the Jackson Laboratory (Bar Harbor, ME). TCR transgenic mice expressing a TCR specific for PLP139–151 (SB6) on the SJL/J background were the kind gift of V. Kuchroo (Harvard) and were bred in-house at Northwestern University. MARC-γ mice on the BALB/c background were kindly provided by L. Kobzik (Harvard). All mice were housed under specific pathogen-free conditions in the Northwestern University Center for Comparative Medicine and maintained according to protocols approved by the Northwestern University Institutional Animal Care and Use Committee.

Peptides. PLP139–151 (HSLGKWLGHPDKF), MOG35–55 (MEGVYGRSFPVYHLYRNGK) and OVA323–329 (ISQAVHAAHAEINEAGR) were purchased from Genemed Synthesis. PLP178–191 (NTWTTCCQIAFPSK) was purchased from Peptides International.

Induction and clinical evaluation of peptide-induced EAE. Peptide-induced and adoptive-transfer EAE was induced in SJL/J mice as previously reported48,49. Individual mice were observed daily, and clinical scores were assessed in a blinded fashion on a 0–5 scale as follows: 0, no abnormality; 1, limp tail or hindlimb weakness; 2, limp tail and hindlimb weakness; 3, hindlimb paralysis; 4, hindlimb paralysis and forelimb weakness; and 5, moribund.

Tolerance induction with antigen-coupled cells and microparticles. Tolerance was induced by i.v. injection of chemically treated Ag-SP, as described previously11,18. Briefly, spleens were removed from naive female mice, and the red blood cells were lysed. The splenocytes were incubated with ECDI (150 mg per 3.2 × 10⁶ cells; Calbiochem) and peptide (1 mg/ml) on ice, shaking for 1 h. The coupled cells were washed three times and filtered through a 70-µm cell strainer to remove cell clumps. The Ag-SP were resuspended at 250 × 10⁶ cells/ml in PBS. Each mouse received 50 × 10⁶ Ag-SP in 200 µl of PBS given by i.v. injection at the indicated times before disease induction. This dosage represents delivery of a total of 15–20 µg of cell-bound peptide per mouse. Carboxylated PSB of various diameters were purchased from Polysciences (Warrington, PA). Peptide antigens were attached to particles using ECDI according to manufacturer’s instructions (12.5 mg of polystyrene microparticles and 500 µg of peptide in the presence of 10 mg/ml ECDI). Five-hundred–nanometer carboxylated PLG microparticles were purchased from Polysciences, Inc. (Fall River, MA), and peptide antigens were attached using ECDI as for the PSB. Mice received intravenous injections of approximately 9 × 10⁹ microparticles comprising 15–20 µg of peptide, depending on the sequence used in the coupling reaction.

Antibodies and flow cytometry. Cells were isolated from the spleen or CNS as previously described49. Briefly, FcR blocking with CD16/32 (clone 2.4G2) was performed, followed by staining with various combinations of antibodies to the following: CD69 (clone H1.2F3)–allophycocyanin (APC), CD69–FITC, CD62L (clone MEL14)–APC/AlexaFluor750, CD44 (clone IM7)–phycoerythrin (PE)/Cy7, Foxp3 (clone FJK-16D)–APC, Foxp3–PE/Cy7, CD152 (clone UC10–4B9)–PE, PD-1 (clone MIH5)–PE, IFN-γ (clone XMG1.2)–PE/Cy7, CD25 (clone 1:2B71)–APC, CD90.1 (clone H1S51)–Pacific Blue and CD45 (clone 30–F11)–PE, all of which were purchased from eBioscience. CD25 (clone PC61)–FITC and CD25–APC, CD3 (clone 145.2C11)–APC/Alexa750 and CD4 (clone GK1.5)–PerCP were purchased from Becton Dickinson. Cytometric data were collected on a FACS Canto flow cytometer (Becton–Dickinson). DiVa software was used for data acquisition and analysis (Becton–Dickinson).

DTH and in vitro proliferation assays. DTH was performed by a 24 h ear swelling assay as previously reported41. Prechallenge ear thickness was determined using a Mitutoyo model 7326 engineer’s micrometer (Schlesinger’s Tools, Brooklyn, New York). Immediately after, DTH responses were elicited by injecting 10 µg of peptide in 10 µl of PBS into the dorsal surface of the ear using a 100-µl Hamilton syringe fitted with a 30 gauge needle. The increase in ear thickness over the prechallenge measurements was determined 24 h after ear challenge. Results are expressed in units of 10⁻⁴ inches ± s.e.m. For proliferation assays, draining lymph nodes (axillary, brachial and inguinal) and/or spleens were harvested from naive mice or primed mice at the indicated times after disease induction, counted and cultured in 96-well microtiter plates at a density of 5 × 10⁶ cells per well in a total volume of 200 µl of HL-1 medium (BioWhittaker; 1% penicillin and streptavidin and 1% glucose). Cells were cultured at 37 °C with medium alone or with different concentrations of peptide antigen for 72h. During the last 24 h, cultures were pulsed with 1 µCi per well [³H]Thd, and uptake was detected using a Topcount microplate scintillation counter. Results are expressed as the mean of triplicate cultures. IFN-γ and IL-17 concentrations were determined by Liqui-Chip analysis.

Treg cell inactivation. Naïve T cells were isolated from the lymph nodes of healthy 5B6 mice by magnetic separation. Single-cell preparations of nodes were prepared, FcR blocked with 2.4G2 and labeled with CD4¹ T cell isolation reagents (Miltenyi Biotec). T cells were isolated using an AutoMACS magnetic separator (Miltenyi Biotec). Ninety-four to ninety-eight percent purity was routinely achieved. After isolation, 20 × 10⁶ T cells per ml were fluorescently labeled in a 4 µm solution of carboxyfluorescein diacetate in PBS for 8 min at room temperature. The reaction was quenched by addition of a half volume of heat-inactivated FBS and an additional 5 min incubation at room temperature. Cells were washed twice in PBS before injection into the lateral tail vein of recipient mice (5 × 10⁶ T cells per recipient). Forty-eight hours after transfer, recipient mice were treated with a variety of antigen-coupled microparticles or with antigen in CFA. At various times after treatment, spleens and lymph nodes were isolated, and transgenic T cells (identifiable by CD90.1 and transgene expression) in these organs were analyzed for cell division and a variety of surface and intracellular markers as described above.

Immunohistochemistry. Mice were infused with PBS or FITC-labeled MOG35–55–PSB. Eighteen hours after infusion, spleens were dissected, fixed in paraformaldehyde for 30 min to 3 h at 4 °C in the dark and snap frozen in optimal cutting temperature compound. The blocks were stored at −80 °C in plastic bags to prevent dehydration. Six-micrometer–thick cross-sections were cut on a Reichert-Jung cryocut CM1850 cryostome (Leica), mounted on Superfrost Plus electrostatically charged slides (Fisher), air dried and stored at −80 °C. Slides were stained using the Tyramide Signal Amplification Direct kit (NEN) according to the manufacturer’s instructions. Nonspecific staining was blocked using either Ab that recognizes both CD16 and CD32 (FcII/II, 2.4G2; BD Pharmingen) or 10% horse serum, as well as an avidin and biotin blocking kit (Vector Laboratories) in addition to the blocking reagent provided by the Tyramide Signal Amplification kit (NEN). Sections were then stained with primary [MARCO (BAF2956), SIGN-R1 (BAF1836) or SIGLEC-1 (BAF5610)] and secondary antibodies, as well as DAPI as previously described42. Sections were overlaid with Vectashield mounting medium with DAPI (Vector Laboratories), and images were acquired using a Lica DM5000B fluorescent microscope and Advanced SPOT software. At least eight serial sections from each sample per group were analyzed at × 20, × 40 and × 100 magnification.

Statistical analyses. Comparisons of DTH responses, mean clinical disease scores, proliferation, cytokine responses or mean fluorescence intensities between any two groups of mice were analyzed by a standard two-tailed t test or one-way ANOVA, depending on the precise comparisons made. P < 0.05 was considered significant.
